# p8130 HW4 Regression

Eleanor Zhang 11/11/2018

#### Problem 2 Heart disease

We are interested in fi there is an association between **total cost** in dollars diagnosed with heart disease and the **number of ER visits**. Other factors will be adjusted later on.

### a) short description of data and look at the data

```
heart disease <- read csv("./data/HeartDisease.csv")
## Parsed with column specification:
## cols(
##
     id = col_integer(),
##
     totalcost = col_double(),
     age = col_integer(),
##
     gender = col_integer(),
##
##
     interventions = col_integer(),
##
     drugs = col_integer(),
     ERvisits = col_integer(),
##
##
     complications = col_integer(),
##
     comorbidities = col_integer(),
##
     duration = col_integer()
## )
head(heart disease)
```

## # A tibble: 6 x 10										
##		i	d tot	talcost	age	gender	${\tt interventions}$	drugs	${\tt ERvisits}$	complications
##		<int< td=""><td>&gt;</td><td><dbl></dbl></td><td><int></int></td><td><int></int></td><td><int></int></td><td><int></int></td><td><int></int></td><td><int></int></td></int<>	>	<dbl></dbl>	<int></int>	<int></int>	<int></int>	<int></int>	<int></int>	<int></int>
##	1		1	179.	63	0	2	1	4	0
##	2		2	319	59	0	2	0	6	0
##	3		3	9311.	62	0	17	0	2	0
##	4		4	281.	60	1	9	0	7	0
##	5		5	18727.	55	0	5	2	7	0
##	6		6	453.	66	0	1	0	3	0
##	#		with 2 more variables: comorbidities <int>, duration <int></int></int>						<int></int>	

In this dataset, there are 788 observations of patients with 10 variables:

- id: patient id
- totalcost: total cost (\$) of patients who are diagnosed with heart disease
- age: age of patients
- interventions: number of interventions (integers)
- drugs: ? number of drugs.
- ERvisits: number of ER visits
- complications: number of complications
- comorbidities: number of co-presence of other diseases in additional to heart disease
- duration: duration of heart disease (in days)

Based our investigation interest, the main outcome is **total cost** of patients with heart disease and the main predictor is **ERvisits** (number of ER visits). Other important covariates also need to be considered because they could potential have differential effect on the association relationship between out main predictor and main outcome, including age, interventions, drugs used, complications, and duration of disease. We will first take a look at these variables:

i) First we took a look at the main outcome and main predictor

```
variable_set1 <- dplyr::select(heart_disease, totalcost, ERvisits, everything(), -c(id, gender, complic
variable_set2 <- dplyr::select(heart_disease, gender, complications)
knitr::kable(summary(variable_set1))</pre>
```

#prop.table(table(variable_set2))
Visualize the distribution of these variables
```

```
par(mfrow = c(1,2))
hist(variable_set1$totalcost)
```

hist(variable\_set1\$ERvisits)

number summaries for variables:

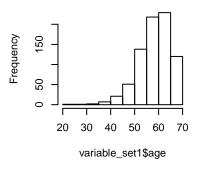

# Histogram of variable\_set1\$totalc Histogram of variable\_set1\$ERvis

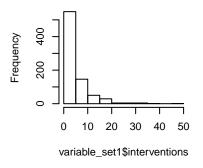

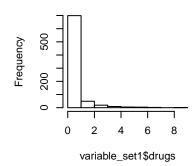

Comment: Since total cost and ER visits are both heavily right skewed on the histograms, we better use median and IQR in the summay table to describe them. Especially for total cost, there are many extreme values at the right tail end which needed to be investigated further in the following analysis.

```
par(mfrow = c(2,3))
hist(variable_set1$age)
hist(variable_set1$interventions)
hist(variable_set1$drugs)
hist(variable_set1$comorbidities)
hist(variable_set1$duration)
```

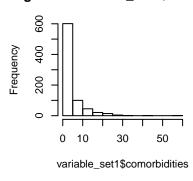

### Histogram of variable\_set1\$agstogram of variable\_set1\$interve Histogram of variable\_set1\$dru

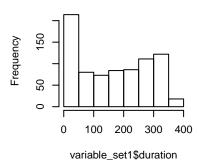

### stogram of variable\_set1\$comorkHistogram of variable\_set1\$dura

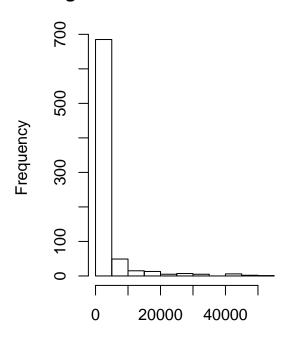

Comment: age is slightly left skewed which means elder people have been overly sampled. The median of intervention is about 5 with large IQR of 5. drugs?. Commordities have median of 3.7 with large IQR 5. Duration of heart disease is roughly uniformly distributed from 50 to 350 days with median 165 days and IQR 240 days. Therefore, these co-variables are not normally distributed in the sample, so we need to adjust for this in later analysis.

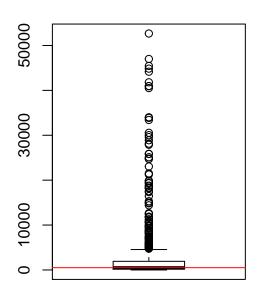

#### b) investigate the shape of distribution for total cost

raw data of total cost

```
par(mfrow = c(1,2))
hist(heart_disease$totalcost)
boxplot(heart_disease$totalcost)
abline(median(heart_disease$totalcost), 0, col = "red")
```

# Histogram of heart\_disease\$totalc

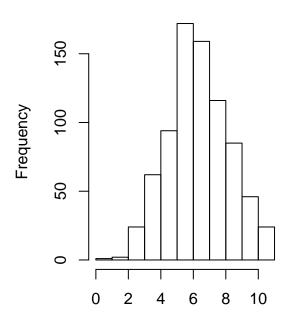

heart\_disease\$totalcost

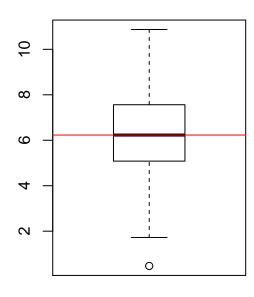

Then we try log transformation on **totalcost** to see if this will transform the distribution.

```
heart_disease <- mutate(heart_disease, log_totalcost = log(totalcost))
par(mfrow = c(1,2))
hist(heart_disease$log_totalcost)
boxplot(heart_disease$log_totalcost)

## Warning in bplt(at[i], wid = width[i], stats = z$stats[, i], out =
## z$out[z$group == : Outlier (-Inf) in boxplot 1 is not drawn
abline(median(heart_disease$log_totalcost), 0, col = "red")</pre>
```

# listogram of heart\_disease\$log\_tota

heart\_disease\$log\_totalcost

comment: After log transformation, we saw a pretty good bell shape of the ditribution. So we will use this transformed data as needed.

### c) dichotomize complications

```
heart_disease <- heart_disease %>%
  mutate(comp_bin = ifelse(complications == 0, 0, 1))
```

#### d) fit linear model SLR

Min

## -6.6454 -1.1195 0.0371

1Q Median

3Q

1.2872

From part (b), we saw the transformed data look better in normal shape, we will use the transformed data to fit SLR. So we fit a simple linear regression model between outcome  $log\_totalcost$  and predictor ERvisits. Let  $Y_i = response(total cost)$ ,  $X_i = predictor$  (ERvisits).

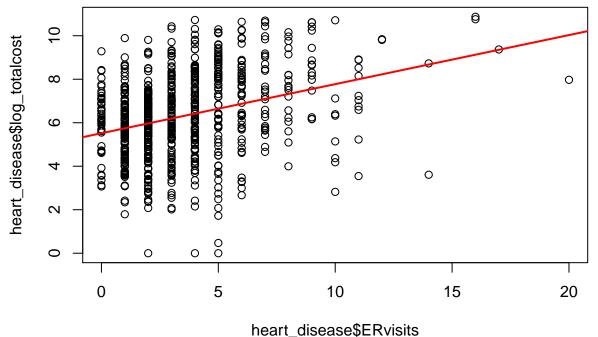

Then our model is  $log Y_i = \beta_0 + \beta_1 X_i + \epsilon_i$ . Here it is reasonable to assume the error is normally distributed because the log transformation improve normality. then assume  $\epsilon_i \sim N(0, \sigma^2)$ 

```
# modify log transformed data
heart_disease$log_totalcost[is.infinite(heart_disease$log_totalcost)] = 0
SLR <- lm(log_totalcost ~ ERvisits, data = heart_disease)
summary(SLR)
##
## Call:
## lm(formula = log_totalcost ~ ERvisits, data = heart_disease)
##
## Residuals:</pre>
```

Max

                                      9.214
                                              <2e-16 ***
##
                     '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
## Signif. codes:
##
## Residual standard error: 1.812 on 786 degrees of freedom
## Multiple R-squared: 0.09749,
                                     Adjusted R-squared:
## F-statistic: 84.91 on 1 and 786 DF, p-value: < 2.2e-16
plot(heart_disease$ERvisits, heart_disease$log_totalcost)
abline(SLR, col = "red", lwd = 2)
```

The result of regression tells that the fitted model is:

$$log Y_i = 5.517 + 0.23 X_i$$

Interpretation: The fitted model indicates that for every unit increase in ER visits, the total cost in dollars on logarithm scale will increase by 0.23. when the ER visit is zero, the total cost in dollar on logarithm scale will be 5.517. The p value for two estimators  $\beta_0$  and  $\beta_1$  are well below 0.001. So we are very confident that there is a strong association between total cost and ER visits, and our simple regression model describes their relationship.

### e) fit MLR with comp\_bin and ERvisits

i) test if **comp\_bin** is an effect modifier of the relationship between **totalcost** and **ERvisits** Let  $Y_i = \text{response}(\text{total cost})$ ,  $X_{i1} = \text{predictor}(\text{ERvisits})$ ,  $X_{i2} = \{\text{when comp\_bin equals 1, otherwise equals 0}\}$ 

The full model is:  $log Y_i = \beta_0 + \beta_1 X_i + \beta_2 X_{i2} + \epsilon_i$ 

```
Now add in a potential modifier: log Y_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i1} X_{i2} + \epsilon_i
So our hypothesis statement is: H_0: \beta_3 = 0 vs. H_a: \beta_3 \neq 0
MLR_comp <- lm(log_totalcost ~ ERvisits + comp_bin, data = heart_disease)
MLR_comp_inter <- lm(log_totalcost ~ ERvisits + comp_bin + ERvisits*comp_bin, data = heart_disease)

        784 2461.5 1
                           3.1915 1.0165 0.3137
```

Based on the regression result, p value for the interaction coefficient  $\beta_3$  is 0.314, which is quite large. So at 0.95 significance level, we do not have evidence to reject the null. Therefore we is no interaction or modifier effect of complications in the relationship between total cost and ER visits.

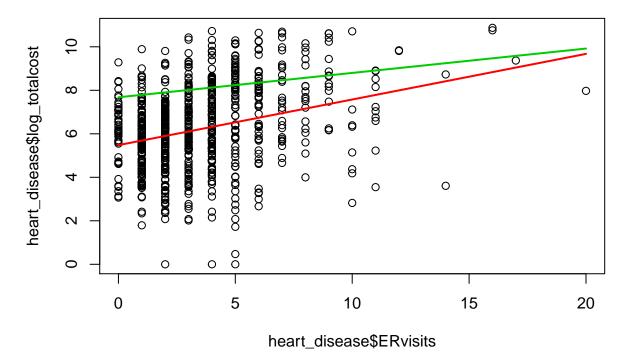

To visualize interaction model:

```
range(heart_disease$ERvisits)
```

```
## [1] 0 20
ER <- seq(0,20,0.5)
beta <- MLR_comp_inter$coefficients

# comp_bin = 0
yhat1 <- beta[1] + beta[2]*ER
# comp_bin greater than 0
yhat2 <- beta[1] + beta[3] + (beta[2] + beta[4])*ER

plot(heart_disease$ERvisits, heart_disease$log_totalcost)
lines(ER, yhat1, col = 2, lwd = 2) # comp_bin = 0
lines(ER, yhat2, col = 3, lwd = 2) # comp_bin greater than 0</pre>
```

ii) test if **comp\_bin** is a confounder of relationship between total cost and ERvisits

```
Model 1 without comp_bin: log Y_i = \beta_0 + \beta_1 X_i + \epsilon_i
```

Model 2 with comp\_bin:  $log Y_i = \beta_0 + \beta_1 X_i + \beta_2 X_{i2} + \epsilon_i$ 

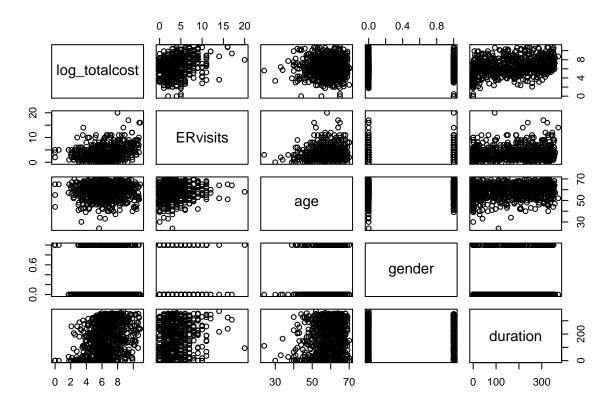

```
SLR <- lm(log_totalcost ~ ERvisits, data = heart_disease)
MLR_comp <- lm(log_totalcost ~ ERvisits + comp_bin, data = heart_disease)
anova(SLR, MLR_comp)</pre>
```

```
